# Scheduling with Machine-Dependent Priority Lists 

University

## Tami Tamir

Based on joint work with
Vipin Ravindran Vijayalakshmi and
Marc Schroder

## Traditional Scheduling Algorithms

- A centralized authority (a scheduler) determines the outcome.
- The centralized authority aims to maximize the system's utilization and the total users' welfare.
- All the users obey it.

## Job Scheduling Games

- The jobs are controlled by selfish agents who select the jobs assignment.
- No centralized authority.

Every job selects its machine, trying to maximize its own utility

## Coordinated Mechanism

Machines have a local scheduling policy.
The jobs know this policy and select their machine accordingly.

Example: Assume that all the machines schedule the jobs in LPT (Longest first) order.

## Coordinated Mechanism LPT Policy

Which machine should I join to minimize my completion time?

$$
\mathrm{p}_{1}=5
$$

| 7 | 7 | 5 | 2 |
| :--- | :--- | :--- | :--- | :--- |

$C_{j}=7+7+5=19$ if j join $\mathrm{M}_{2}$

$\square$ $C_{j}=8+5=13$ if l join $\mathrm{M}_{1}$

## If the local policy is LPT, I'Il better join $\mathrm{M}_{1}$.

This is my best-response.

## Coordinated Mechanism SPT Policy <br> 

| $M_{1}$ | 3 | 4 | 8 |
| :--- | :---: | :---: | :---: |
|  | 3 | 4 |  |
| $M_{2}$ | 2 | 7 | 7 |
|  |  |  |  |

| $M_{2}$ | 2 | 5 | 7 | 7 |
| :--- | :--- | :--- | :--- | :--- |
|  |  |  |  |  |

$C_{j}=2+5=7$ if I join $M_{2}$

| $M_{1}$ | 3 | 4 | 5 | 8 |
| :--- | :--- | :--- | :--- | :--- |

|  |  |  |  |
| :--- | :--- | :--- | :--- |
|  | 2 | 7 | 7 |
|  | 2 |  |  |
|  |  |  |  |

$C_{j}=3+4+5=12$ if $I$ join $M_{1}$
(2) If the local policy is SPT, my best-response is to join $\mathrm{M}_{2}$.

## Coordinated Mechanism SPT Policy

Assume that
joins $\mathrm{M}_{2}$

Consider the $2^{\text {nd }}$ job of length 7 in the resulting schedule

## Coordinated Mechanism SPT Policy

|  | 2 | 5 | 7 |
| :---: | :---: | :---: | :---: |

Now, other jobs may have a beneficial migration...

## Best Response Dynamics (BRD)

- A local search method.
- Players proceed in turns, each performing a selfish improving step.
- An important question: Does BRD converge to a pure Nash equilibrium.

A stable profile in
which no player has
an improving step.

## Our Work

We study coordinated mechanisms in which different machines may have different local policies.

For the associated game, we analyzed:

- Nash equilibrium existence and calculation
- BRD convergence
- Equilibrium inefficiency

Not less important: We studied the centralized version of this setting.

## The Setting

- A set J of n jobs

- Every job $j \in J$ has processing time $p_{j}$
- A set M of $m$ parallel machines
- Every machine $i \in M$ has speed $s_{i}$ and a priority list $\pi_{i}: J \rightarrow\{1, \ldots, n\}$, defining its scheduling policy.

$$
\pi_{1}=\left(\begin{array}{lllll}
0 & 0 & 0 & 0 & 00 \\
1 & 2 & 3 & 4 & \frac{b}{5}
\end{array}\right)
$$

## The Setting

$$
\begin{aligned}
& \text { Example: J=\{ } \begin{array}{lllllll}
0 & b & c & 0 & 0 \\
p_{j}= & 2 & 4 & 2 & 2 & 1
\end{array} \quad \text { processing times } \\
& \mathrm{m}=2 \text {, } \\
& s_{1}=1 \quad \pi_{1}=(e, d, c, b, a) \\
& s_{2}=0.5 \quad \pi_{2}=(a, b, c, d, e)
\end{aligned}
$$

A profile of the game:
A schedule $\sigma$ : $J \rightarrow M$.
$\mathrm{C}_{\mathrm{j}}(\sigma)=$ the completion time of job j in profile $\sigma$

$$
C_{j}=(4,7,8,3,1)
$$

## The Setting

$$
\begin{aligned}
& \text { Example: J=\{ } \begin{array}{lllllll}
0 & b & c & 0 & 0 \\
p_{j}= & 2 & 4 & 2 & 2 & 1
\end{array} \quad \text { processing times } \\
& \mathrm{m}=2 \text {, } \\
& s_{1}=1 \quad \pi_{1}=(e, d, c, b, a) \\
& s_{2}=0.5 \quad \pi_{2}=(a, b, c, d, e)
\end{aligned}
$$

Does anyone have a beneficial migration?

## The Setting

$$
\begin{aligned}
& \mathrm{m}=2 \text {, } \\
& s_{1}=1 \quad \pi_{1}=(e, d, c, b, a) \\
& s_{2}=0.5 \quad \pi_{2}=(a, b, c, d, e)
\end{aligned}
$$

| $M_{1}$ | $e$ | $d$ | $c$ | $b$ |
| :--- | :--- | :--- | :--- | :--- |
|  |  |  |  |  |

## Game Theory Definitions

A profile is a pure Nash equilibrium (NE) if no job can reduce its completion time by changing its strategy (migrating to a different machine)

A social optimum (SO) of a game is a profile that attains some optimality criteria.
For example:
social optimum w.r.t total flow time (=sum of $\mathrm{C}_{\mathrm{j}}$ ) social optimum w.r.t makespan (=maximal $C_{j}$ ).

SO = Optimal solution for the centralized
problem P| $|\pi| C_{\text {max }}$ or $\mathrm{P}|\pi| \Sigma_{j} C_{j}$

## Interesting Questions

- Calculating a NE for a given game instance
- What is the equilibrium inefficiency?

$$
\begin{aligned}
& \text { Price of Anarchy }=\text { wof } \begin{array}{l}
\text { def } \\
\text { Price } \\
\text { PE } \\
\text { Stability }
\end{array}=\text { best } \text { de } / \text { SO }
\end{aligned}
$$

- Convergence of Best-Response Dynamics

## Back to our example

$$
\begin{array}{ll}
s_{1}=1 & \pi_{1}=(e, d, c, b, a) \\
s_{2}=0.5 & \pi_{2}=(a, b, c, d, e)
\end{array}
$$

$C_{\text {max }}=8$
A social optimum w.r.t Makespan, but not a NE.

A possible NE profile.

$$
C_{\max }=9
$$

Price of anarchy $\geq 9 / 8$

Selfish Scheduling / Coordinated mechanism /Prioritybased model of routing/ The centralized problem.

## NE Calculation

Given $\left\langle J, M,\left\{s_{i}\right\},\left\{\pi_{i}\right\}\right\rangle$, calculate a NE profile

## NE existence

$$
\begin{array}{lr}
\mathrm{m}=3, \mathrm{M}=\left\{\mathrm{M}_{1}, \mathrm{M}_{2}, M_{3}\right\} \\
\mathrm{s}_{1}=1 & \pi_{1}=(a, b, c, d, e) \\
\mathrm{s}_{2}=s_{2}=0.5 & \pi_{2}=\pi_{3}=(e, d, b, c, a)
\end{array}
$$

One fast machine.
Two slow machines

## NE existence

$s_{3}=0.5, \pi_{3}=(e, d, b, c, a)$
$s_{2}=0.5, \pi_{2}=(e, d, b, c, a)$
$s_{1}=1, \quad \pi_{1}=(a, b, c, d, e)$

Since $a$ is the first on $\pi_{1}$, it is first on $\mathrm{M}_{1}$ in any NE schedule.

## NE existence

$s_{3}=0.5, \pi_{3}=(e, d, b, c, a)$
$s_{2}=0.5, \pi_{2}=(e, d, b, c, a)$
$s_{1}=1, \quad \pi_{1}=(a, b, c, d, e)$

Given that ${ }^{\text {a }}$ is on $M_{1}$, Since e is the first on $\pi_{2}$, it is first on $M_{2}$ (w.l.o.g) in any NE schedule

## NE existence

$s_{3}=0.5, \pi_{3}=(e, d, b, c, a)$
$s_{2}=0.5, \pi_{2}=(e, d, b, c, a)$
$s_{1}=1, \quad \pi_{1}=(a, b, c, d, e)$

So we know that if a NE exists, then and e are first on $\mathrm{M}_{1}$ and $M_{2}$, respectively. Let's consider the possible locations of job d

## NE existence

Therefore, there is no NE in which $d$ is on $M_{1}$

## NE existence

Therefore, there is no NE in which $d$ is on $M_{2}$

## NE existence

$s_{3}=0.5, \pi_{3}=(e, d, b, c, a)$
$s_{2}=0.5, \pi_{2}=(e, d, b, c, a)$
$s_{1}=1, \quad \pi_{1}=(a, b, c, d, e)$

Therefore, there is no NE in which $d$ is on $M_{3}$

## NE existence

We conclude that there are games in which a NE does not exist

## NE existence

## Can we characterize games that have a NE?

Unfortunately, No.

Theorem: Given an instance of a scheduling game, it is NP-complete to decide whether the game has a NE.
Proof: Reduction from 3-bounded 3-dimensional matching

## On the other hand:

We identified four classes of games for which a NE is guaranteed to exist.
$\mathcal{G}_{1}$ : Unit Jobs
$\mathcal{G}_{2}$ : Two machines
$\mathcal{G}_{3}$ : Identical machines
$\mathcal{G}_{4}$ : Global priority list

Note: This characterization is tight. In our No-NE example, there are three machines, two of them are identical (same speed and same priority list)

## For each of the four classes, we present:

- A polynomial time algorithm for computing a NE
- A proof that BRD converges to a NE
- Tight analysis of the equilibrium inefficiency:

| Objective <br> Instance class | Makespan | Sum of Completion <br> Time <br> PoA and PoS |
| :--- | :---: | :---: |
| $\mathcal{G}_{1}:$ Unit Jobs | 1 | 1 |
| $\mathcal{G}_{2}:$ Two machines | $\frac{\sqrt{5}+1}{2}$ | $\Theta(n)$ |
| $\mathcal{G}_{3}:$ Identical machines | $2-\frac{1}{m}$ | $\Theta\left(\frac{n}{m}\right)$ |
| $\mathcal{G}_{4}:$ Global priority list | $\Theta(m)$ | $\Theta(n)$ |

## Two machines

Theorem: If $m=2$, then a NE exists and can be calculated efficiently.

Proof: Algorithm

## Two machines

## Algorithm:

1. Assign all the jobs on $M_{1}$ according to $\pi_{1}$.
2. For $k=1, \ldots, n$, let job $j$ for which $\pi_{2}(j)=k$ perform a best-response move.

$$
\mathrm{M}_{2} \quad \mathrm{~s}_{2} \leq 1
$$

$$
\begin{array}{ll|l|l|l|l|l|}
M_{1} & s_{1}=1 & j_{1} & j_{2} & j_{3} & j_{4} & \ldots \\
\hline j_{n} & \pi_{1}=\left(j_{1}, j_{2}, j_{3}, \ldots, j_{n}\right)
\end{array}
$$

## Two machines

Claim: The algorithm produces a NE.

## Proof:

Let $\sigma$ denote the schedule produced by the algorithm.

1. Jobs on $M_{1}$ have no incentive to deviate (easy).
2. Suppose a job j on $M_{2}$ has an incentive to deviate.

Let $\Delta$ be the set of jobs that have a higher priority on $M_{1}$ than j and moved to $\mathrm{M}_{2}$ after j .

Before j was considered
now
by the algorithm

$$
\begin{aligned}
& \pi_{1}=(\ldots, \Delta, \ldots, B, \ldots) \\
& \pi_{2}=(\ldots, B, \ldots, \Delta, \ldots)
\end{aligned}
$$

## Two machines

(i) $P_{A}+p_{j}<\left(P_{B}+p_{j}\right) / s_{2}$
(ii) $\left(P_{B}+p_{j}+P_{\Delta}\right) / s_{2}<P_{A}+P_{\Delta}$

$$
\Longleftrightarrow p_{j}+P_{\Delta} / s_{2}<P_{\Delta}
$$

A Contradiction (since $\mathrm{p}_{\mathrm{j}} \geq 0$ and $\mathrm{s}_{2} \leq 1$ )

## Two machines

Remark: A possible generalization of our setting considers unrelated machines ( $\mathrm{p}_{\mathrm{ij}}$ is the processing time of job if processed on machine j ).

In this environment, a NE need not exist already with only two unrelated machines.

## Equilibrium inefficiency

The makespan of a profile $\sigma$, is $C_{\max }(\sigma)=\max _{j \in J} C_{j}(\sigma)$
For a game $G$,

$$
\operatorname{PoA}(G)=\frac{\max _{\sigma \in N E(G)} C_{\max }(\sigma)}{\min _{\sigma^{*}} C_{\max }\left(\sigma^{*}\right)}=\frac{\text { makespan of the worst NE schedule }}{\text { min makespan (social optimum) }}
$$

For a class of games $\mathcal{G}$, define $\operatorname{PoA}(\mathcal{G})=\sup _{G \in \mathcal{G}} \operatorname{PoA}(G)$

## Equilibrium inefficiency

The makespan of a profile $\sigma$, is $C_{\max }(\sigma)=\max _{j \in J} C_{j}(\sigma)$
For a game $G$,

$$
\operatorname{PoA}(G)=\frac{\max _{\sigma \in N E(G)} C_{\max }(\sigma)}{\min _{\sigma^{*}} C_{\max }\left(\sigma^{*}\right)}=\frac{\text { makespan of the worst NE schedule }}{\text { min makespan (social optimum) }}
$$

For a class of games $\mathcal{G}$, define $\operatorname{PoA}(\mathcal{G})=\sup _{G \in \mathcal{G}} \operatorname{PoA}(G)$

| Instance class | Makespan PoA |
| :--- | :---: |
| $\mathcal{G}_{1}:$ Unit Jobs | 1 |
| $\mathcal{G}_{2}:$ Two machines | $\frac{\sqrt{5}+1}{2}$ |
| $\mathcal{G}_{3}:$ Identical machines | $2-\frac{1}{m}$ |
| $\mathcal{G}_{4}:$ Global priority list | $\Theta(m)$ |

## Equilibrium inefficiency, two machines.

Theorem: Let G be a game played on two machines, $\mathrm{s}_{1}=1$ and $s_{2} \leq 1$, then $\operatorname{PoA}(G) \leq \min \left\{1+s_{2}, 1+\frac{1}{1+s_{2}}\right\}$

Since $1+s=1+\frac{1}{1+s}$ for $s=\frac{\sqrt{5}-1}{2}$, the theorem implies that $\operatorname{PoA}\left(\mathcal{G}_{2}\right) \leq \frac{\sqrt{5}+1}{2}$.

## Equilibrium inefficiency, two machines.

Theorem: Let G be a game played on two machines, $\mathrm{s}_{1}=1$
and $s_{2} \leq 1$, then $\operatorname{PoA}(G) \leq \min \left\{1+s_{2}, 1+\frac{1}{1+s_{2}}\right\}$
Proof: Let $\sigma$ be a NE.

1. $\quad C_{\max }(\sigma) \leq \sum_{j \in J} p_{j}$
(if all jobs on fast machine)
2. $\quad C_{\max }\left(\sigma^{*}\right) \geq \frac{\sum_{j \in J} p_{j}}{1+s_{2}}$
(balanced)

Implying that $\quad C_{\max }(\sigma) \leq\left(1+s_{2}\right) \cdot C_{\max }\left(\sigma^{*}\right)$.

## Equilibrium inefficiency, two machines.

Theorem: Let G be a game played on two machines, $\mathrm{s}_{1}=1$ and $s_{2} \leq 1$, then $\operatorname{PoA}(G) \leq \min \left\{1+s_{2}, 1+\frac{1}{1+s_{2}}\right\}$

Proof: Let a be the last job to complete in a NE $\sigma$.

1. $C_{\max }(\sigma) \leq p_{a}+\sum_{j \neq a: \sigma_{j}=1} p_{j} \quad$ (a can go to fast machine)
2. $C_{\max }(\sigma) \leq\left(p_{a}+\sum_{j \neq a: \sigma_{j}=2} p_{j}\right) / s_{2} \quad$ (a can go to slow machine) Implying that

$$
\left(C_{\max }(\sigma) \geq p_{a}\right)
$$

$$
C_{\max }(\sigma) \leq \frac{p_{a}+\sum_{j \in J} p_{j}}{1+s_{2}} \leq\left(1+\frac{1}{1+s_{2}}\right) \cdot C_{\max }\left(\sigma^{*}\right)
$$

## Equilibrium inefficiency, two machines.

Theorem: For every $s \leq 1$, there exists a game with $s_{1}=1$, $s_{2}=s$, and $\operatorname{PoS}(G)=\min \left\{1+s, 1+\frac{1}{1+s}\right\}$.

$$
\operatorname{PoS}(G)=\frac{\text { makespan of the best NE schedule }}{\min \text { makespan (social optimum) }}
$$

## Equilibrium inefficiency, two machines.

Theorem: For every $s \leq 1$, there exists a game with $s_{1}=1$, $s_{2}=s$, and $\operatorname{PoS}(G)=\min \left\{1+s, 1+\frac{1}{1+s}\right\}$.
Proof: case 1: $\mathrm{s} \leq \frac{\sqrt{5}+1}{2}$.
Let $\mathrm{J}=\{\mathrm{x}, \mathrm{y}\}, \mathrm{p}_{\mathrm{x}}=1, \mathrm{p}_{\mathrm{y}}=\frac{1}{s}$

$$
\pi_{1}=\pi_{2}=(x, y) .
$$

$$
\begin{aligned}
& 1+s=1+\frac{1}{1+s} \\
& \text { for } s=\frac{\sqrt{5}-1}{2}
\end{aligned}
$$

$\left.{ }^{*}\right)$ if $s=\frac{\sqrt{5}-1}{2}$, take $p_{y}=\frac{1}{s}-\epsilon$ )

$$
\mathrm{PoS}=1+\mathrm{s}
$$

## Equilibrium inefficiency, two machines.

case $2: \mathrm{s}>\frac{\sqrt{5}-1}{2}$.
$J=\{x, y, z\}, p_{x}=1, p_{y}=s^{2}+s-1, p_{z}=1+s$.
$\pi_{1}=\pi_{2}=(x, y, z)$.
In all NE: (1) $x$ is on the fast machine
(2) $y$ is on the slow machine since $s^{2}+s>\left(s^{2}+s-1\right) / s$.
(3) $z$ is indifferent. $p_{x}+p_{z}=\left(p_{y}+p_{z}\right) / s=2+s$.

$$
\operatorname{PoS}=\frac{2+s}{1+s}=1+\frac{1}{1+s}
$$

## Equilibrium inefficiency, Identical machines

Theorem:
If $s_{i}=1$ for all $i \in M$, then $\operatorname{PoA}(G) \leq 2-\frac{1}{m}$
Proof:
We show that any NE is a possible outcome of Graham's List-scheduling algorithm

Theorem:
If $s_{i}=1$ for all $i \in M$, then it is NP-hard to approximate the best NE within a factor of $2-\frac{1}{m}-\epsilon$ for all $\epsilon>0$. Proof:
Reduction from 3D-matching.

## Back to centralized setting (not a game)

- A set J of $n$ jobs, and a set $M$ of $m$ parallel machines
- Every job $j \in J$ has processing time $p_{j}$
- In case of unrelated machines, $p_{i j}$ is the processing time of job j on machine i.
- Every machine $i \in M$ has a priority list $\pi_{\mathrm{i}}: J \rightarrow\{1, \ldots, \mathrm{n}\}$, defining its scheduling policy.

The Goal: Find a schedule that minimizes $\sum_{j} C_{j}$

Note: In the centralized setting, priority lists do not `upgrade’ the problem of minimizing the Makespan

## The problems $\mathrm{P}|\pi| \sum_{j} C_{j}$ and $\mathrm{R}|\pi| \sum_{j} C_{j}$

Without priority lists, both problems are solvable
$\mathrm{P}\left|\mid \sum_{j} C_{j}-\mathrm{SPT}\right.$ is optimal [Smith 1956]
$\mathrm{R}\left|\mid \sum_{j} C_{j}\right.$ - can be represented as a bipartite weighted matching problem [Bruno, Coffman, Sethi 1974]

Theorem: $\mathrm{P}|\pi| \sum_{j} C_{j}$ is APX-hard

We therefore consider several restricted classes:

- Global priority list
- Fixed number of machines
- Fixed number of priority classes

## The problems $\mathrm{P}|\pi| \sum_{j} C_{j}$ and $\mathrm{R}|\pi| \sum_{j} C_{j}$

Our results:

|  | $\pi_{i}$ | $\boldsymbol{\pi}_{\text {global }}$ | $\pi_{L P T}$ | $\boldsymbol{\pi}_{i, \boldsymbol{c}}$ | $\pi_{\text {global, }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| P | APX-hard | QPTAS | P | APX-hard | P |
| R | APX-hard | APX-hard | APX-hard | APX-hard | APX-hard |

$\pi_{i, c}$ and $\pi_{g l o b a l, c}$ : the jobs are partitioned into c job classes $\mathrm{J}_{1}, \ldots, \mathrm{~J}_{\mathrm{c}}$. For every $1<\mathrm{k} \leq \mathrm{c}$, every machine processes jobs from $J_{k}$ after it processes jobs from $U_{j<k} J_{j}$. Note: in every optimal schedule, for every $1 \leq \mathrm{i} \leq \mathrm{m}$ and $1 \leq \mathrm{k} \leq \mathrm{c}$, machine i processes jobs of $\mathrm{J}_{\mathrm{k}}$ in SPT order.

## The problems $\mathrm{P}|\pi| \sum_{j} C_{j}$ and $\mathrm{R}|\pi| \sum_{j} C_{j}$

Our results:

|  | $\boldsymbol{\pi}_{\boldsymbol{i}}$ | $\boldsymbol{\pi}_{\text {global }}$ | $\boldsymbol{\pi}_{L P T}$ | $\boldsymbol{\pi}_{\boldsymbol{i}, \boldsymbol{c}}$ | $\pi_{\text {global, }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| P | APX-hard | QPTAS | P | APX-hard | P |
| R | APX-hard | APX-hard | APX-hard | APX-hard | APX-hard |
| In P if m is a constant |  |  |  |  |  |

## The problems $\mathrm{P}|\pi| \sum_{j} C_{j}$ and $\mathrm{R}|\pi| \sum_{j} C_{j}$

A Useful Observation: Let $l_{i}$ denote the number of jobs on machine $i$.
The job with the $k$-th highest priority assigned to machine $i$ contributes exactly $l_{i}+1-k$ times its processing time to the sum of completion times.
the delay-coefficient of the job

$p_{i j}$ is counted $l_{i}+1-\left(l_{i}-2\right)=3$ times in $\Sigma_{\mathrm{j}} \mathrm{C}_{\mathrm{j}}$

## $\pi_{\mathrm{LPT}}$ - Longest Processing Time First

$\pi_{\text {LPT }}$ - every machine processes jobs in LPT order.
$\mathrm{P}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}:$
A global priority list $\pi=(1,2, \ldots, n)$, where $p_{1} \geq p_{2} \geq \ldots \geq p_{n}$.
$\mathrm{R}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}:$
For machine $i, \pi_{i}=\left(1_{i}, 2_{i}, \ldots, n_{i}\right)$, where $p_{i, 1 i} \geq p_{i, 2 i} \geq \ldots \geq p_{i, n i}$.

## An optimal algorithm for $\mathrm{P}\left|\pi_{\mathrm{LpT}}\right| \sum_{j} C_{j}$

Claim: There exists an optimal schedule for $\mathrm{P}\left|\pi_{\text {LPT }}\right| \sum_{j} C_{j}$ in which for some $l_{1} \leq l_{2} \leq \cdots \leq l_{m}$ such that $\sum_{i} l_{i}=n$, it holds that machine $i$ processes the consequent subsequence of $l_{i}$ jobs $1+\sum_{k<i} l_{k}, \ldots, \sum_{k \leq i} l_{k}$.

Illustration of the claim:

Assume $m=3$, then some optimal schedule looks like this:

## An optimal algorithm for $\mathrm{P}\left|\pi_{\mathrm{LpT}}\right| \sum_{j} C_{j}$

Claim: There exists an optimal schedule for $\mathrm{P}\left|\pi_{\text {LPT }}\right| \sum_{j} C_{j}$ in which for some $l_{1} \leq l_{2} \leq \cdots \leq l_{m}$ such that $\sum_{i} l_{i}=n$, it holds that machine $i$ processes the consequent subsequence of $l_{i}$ jobs $1+\sum_{k<i} l_{k}, \ldots, \sum_{k \leq i} l_{k}$.

Illustration of the claim:

| 1 | 2 | 3 | 4 | 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Assume $m=3$, then some optimal schedule looks like this:

## An optimal algorithm for $\mathrm{P}\left|\pi_{\mathrm{LpT}}\right| \sum_{j} C_{j}$

Proof: (for two machines) Assume that we know how many jobs are assigned to each of the machines. W.l.o.g., assume that $l_{1} \leq l_{2}$.
We show that in some optimal schedule, $M_{1}$ processes the $l_{1}$ longest jobs, and $\mathrm{M}_{2}$ processes the $l_{2}$ shortest jobs.

## An optimal algorithm for $\mathrm{P}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$

Consider the $i$-th job on machine 2. This job gets a coefficient of $l_{2}+1-i$.
The shortest possible job that can get this coefficient is job $l_{1}+i$.
Consider a job $i \leq l_{1}$. The minimal coefficient job $i$ can get is $l_{1}+1-i$ (for example, in every schedule, the longest job, has coefficient at least $l_{1}$ ).

## An optimal algorithm for $\mathrm{P}\left|\pi_{\mathrm{LpT}}\right| \sum_{j} C_{j}$

When jobs $j=1, \ldots, l_{1}$ are on $\mathrm{M}_{1}$ and jobs
$j=l_{1}+1, \ldots, l_{2}$ are on $\mathrm{M}_{2}$, every coefficient (on $\mathrm{M}_{2}$ ) is matched with the shortest job that can get this coefficient, and every job (on $\mathrm{M}_{1}$ ) is matched with the minimal coefficient it can get.

## An optimal algorithm for $\mathrm{P}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$

Theorem: $\mathrm{P}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$ is polynomial time solvable.

## Proof: A dynamic programming based on the above claim

## On the other hand:

With unrelated machines, the problem is hard and hard to approximate:

Theorem: $\mathrm{R}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$ is APX-hard

## $\mathrm{R}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$ is APX-hard

Theorem: $\mathrm{R}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$ is APX-hard Proof: (for now, NP-hardness only)
Reduction from vertex-cover
Given a graph G and an integer k, does G have a VC of size k?

VC of
size 2.
For every edge, at
least one endpoint is in the VC

## $\mathrm{R}\left|\pi_{\text {LPT }}\right| \sum_{j} C_{j}$ is APX-hard

Given $\mathrm{G}=(\mathrm{V}, \mathrm{E})$ and k , construct an instance for $\mathrm{R}\left|\pi_{\mathrm{LPT}}\right| \sum_{j} C_{j}$ :
$|V|$ machines, where $M_{i}$ corresponds to node $i \in V$.
The set of jobs consists of two sets D and A .
D includes $|\mathrm{V}|-\mathrm{k}$ dummy jobs. $\forall i, d, p_{i, d}=1$
A includes $|\mathrm{E}|$ jobs, each corresponding to an edge $\mathrm{e} \in \mathrm{E}$.

$$
p_{i,(u, v)}=\left\{\begin{array}{cc}
0 & i=u \text { or } i=v \\
1 & \text { otherwise }
\end{array} \quad i \text { is an endpoint of }(u, v)\right.
$$

$\mathrm{M}=\{\mathrm{a}, \mathrm{b}, \mathrm{c}, \mathrm{d}, \mathrm{e}\}$
$\mathrm{J}=\mathrm{D} \cup \mathrm{A}$
$\mathrm{D}=\left\{\mathrm{d}_{1}, \mathrm{~d}_{2}, \mathrm{~d}_{3}\right\}$
$A=\{(a b),(a d),(a e), \ldots\}$

## $\mathrm{R}\left|\pi_{\text {LPT }}\right| \sum_{j} C_{j}$ is APX-hard

$\pi_{\text {LPT }}$ implies that if a job (edge) is assigned on a machine corresponding to one of its endpoint then it is processed after any dummy job assigned to this machine.

A VC of size $\mathrm{k} \Leftrightarrow$ a schedule with $\sum_{j} C_{j}=|\mathrm{V}|-\mathrm{k}$

Every dummy job goes to a different machine.
All A-jobs have $\mathrm{C}_{\mathrm{j}}=0$.

## $\mathrm{R}\left|\pi_{\text {LPT }}\right| \sum_{j} C_{j}$ is APX-hard

Hardness proof for APX-hardness a bit more technical. The reduction is from Max-k-VC of a bounded degree graph.
Given $G$, $k$, where max-degree $(G)=\Delta$, find $U \subseteq V,|U|=k$, such that the number of edges adjacent to vertices in $U$ is maximal.

## Summary and open problems

- The introduction of machine-dependent priority lists opens a new world of optimization problems.
- Challenging analysis as a game as well as an optimization problem.
- General instances: no guaranteed NE, hard to approx.
- Some important classes behave nicely.

## Summary and open problems

To do list:

- Complexity status of $\mathrm{P}|\pi| \sum_{j} C_{j}$ (QPTAS but no hardness proof)
- Identify additional tractable/stable instances
- Approximation algorithms
- Priority-list can be viewed as a special case of machines-based precedence constraints (precedence constraints given by a chain). Study the general P|machine-based prec $\mid \sum_{j} C_{j}$
- Analyze instances with due-dates and lateness-related obj.

Assume a global priority list.
What is the minimal number of machines required to complete all jobs on time?
